Abstract.

Background. Several trials and meta-analysis have addressed whether bifurcations lesions require stenting of both the main vessel and side branch. The Tryton side brach stent is a bifurcation system that secures the side branch and provides ostial protection. Uncertainty remains on the benefits of such Tryton Stent versus a single (provisional) stenting with regards to the occurrence of periprocedural myocardial infarction (periMI).

Methods. Studies treating bifurcation lesions were searched in Pubmed. The primary end-point was the occurrence of peri-MI. Crude and weighted by the inverse of variance method risks (R) and 95% Confidence Intervals (CI) were computed.

Results. Seventeen studies (n=2924) for the comparison of Tryton stent vs. single stent. The crude risk of peri-MI among patients treated with a single technique and Tryton Stent were 4.42 % (95% CI 3.98-4.86%) and 3.45 % (95% CI 2.79-4.12%), respectively. The risk estimation weighted by inverse variance yield 1.48% (95%CI 1.00-1.98) and 2.78% (95% CI 1.61-3.95%), respectively.

Conclusions. Stenting of both the side branch with a Tryton stent and the main vessel in bifurcation lesions may not reduce the rate of periprocedural myocardial infarction as compared to a provisional one-stent technique.

Table 1. Studies using a provisional stent technique, included in the meta-analysis.

Studies	Reference	Periprocedural MI definition	Periprocedural MI incidence (provisional stent)
BBC-ONE	Heart 2012;98:1431-35 Circulation. 2010;121:1235-1243	CK \geq 3 fold or rise > 50% above previous values	4 / 233
